R-code for "Demographic causes of adult sex ratio variation and their consequences for parental cooperation"

Luke J. Eberhart-Phillips, Clemens Küpper, María Cristina Carmona-Isunza, Orsolya Vincze, Sama Zefania, Medardo Cruz-López, András Kosztolányi, Tom E. X. Miller, Zoltán Barta, Innes C. Cuthill, Terry Burke, Tamás Székely, Joseph I. Hoffman, and Oliver Krüger

February 20, 2018

In this document we provide all the necessary code for reproducing the analyses presented in our paper. To access the dataset and Rmarkdown file, please download this GitHub repository. Simply follow the link and click on *Download ZIP* on the right-hand side of the page. An explanation of the files in the repository can be found in the Readme file. Please don't hesitate to contact Luke at luke.eberhart[at]gmail.com if you have any questions.

The structure of the code we present here roughly follows the analyses presented in the *Supplementary Materials: Methods* section of the paper.

Prerequisites:

- For running the complete code you need a files subfolder containing the raw data downloaded from data and output/bootstrap folders provided in the GitHub repository.
- The following packages are needed for analysis and can be easily installed from CRAN by uncommenting the install.packages functions:

```
# install.packages("RMark")
# install.packages("stringr")
# install.packages("ggplot2")
# install.packages("dplyr")
# install.packages("grid")
# install.packages("qridExtra")
# install.packages("reshape2")
# install.packages("RColorBrewer")
# install.packages("Rmisc")
# install.packages("stats")
# install.packages("lme4")
# install.packages("magrittr")
# install.packages("MultinomialCI")
# install.packages("ggrepel")
# install.packages("truncnorm")
library(RMark)
library(stringr)
library(ggplot2)
library(dplyr)
library(gridExtra)
library(grid)
library(reshape2)
library(reshape)
library(RColorBrewer)
library(Rmisc)
library(stats)
```

```
library(lme4)
library(magrittr)
library(MultinomialCI)
library(ggrepel)
library(truncnorm)
```

Loading data

To start, please load the following datasets into your R environment:

- data/Appendix_B_juvenile_adult_mark-recapture_data.txt contains the mark-recapture field data of juveniles and adults. Each row is a single uniquely marked individual identified by their bird_ID. The annual encounter history of an individual is expressed in their ch, where a "1" indicates that an individual was encountered and "0" indicates it was not encountered. sex describes the molecular sex-type of an individual with "M" for males and "F" for females. age describes the stage at which an individual was initially captured, where "J" indicates it was first captured as a chick, and "A" indicates it was first captured as an adult. population describes the population in which the individual was sampled from ("KIP" = Kittlitz's plover, "MP" = Madagascar plover, "WFP" = white-fronted plover, "KPT" = Kentish plover Tuzla, "KPM" = Kentish plover Maio, and "SP" = snowy plover).
- data/Appendix_B_breeding_data.txt contains the individual reproductive histories of all marked breeding adults in the population. Each row is a nesting attempt uniquely identified by the family_ID. no_chicks expresses the number of chicks that hatched from the nest. clutch_size indicates the number of eggs in the nest when it was initially discovered. year describes the year in which the nest was active. male and female indicates the unique identity of the father and mother, respectively, with "male_NA" and "female_NA" describing cases in which the other mate was not identified. population describes the population in which the individual was sampled from (same notation as above).
- data/Appendix_B_hatching_sex_ratio_data.txt contains the sex and origin of each chick included in our analysis to assess hatching sex ratio. Each row is a chick uniquely identified by their chick_ID. The family of origin for each chick is shown in their family_ID. year describes the year in which the chick hatched. A "1" in either the male or female column indicates the molecular sex-type of a given chick. population describes the population in which the chick was sampled (same notation as above).
- data/Appendix_B_parental_care_data.txt contains the behavioral observations of the care-system for each family. Each row is an observation of a unique family (family_ID) within a given population. care_system expresses the parental care recorded on a given observation (i.e. "male_care", "female_care", or "both_care". hatch_date indicates the date on which a given brood hatched. date indicates the date on which the observation was made (same notation as above).

Parental sex roles

To put our estimate of ASR in the context of breeding behavior, we quantified sex bias in parental care based on behavioral observations from the field.

First, some data formatting. Define the observation data (*date*) and the hatch date (*hatch_date*) variables as a date (*as.Date*, year-month-day):

```
parental_care_data$date <- as.Date(parental_care_data$date, "%Y-%m-%d")
parental_care_data$hatch_date <- as.Date(parental_care_data$hatch_date, "%Y-%m-%d")</pre>
```

Next, calculate the age of each brood when it was observed. Subtract the observation date from the hatch_date. The assign the brood observation into a brood_period describing it's age (early: less than 10 days old, middle: between 10 and 20 days old, late: older than 20 days).

Transform the $care_system$ variable into a numeric to aquire a ranking system of the care levels (i.e., both care = 1, female care = 2, male care = 3).

```
parental_care_data$care_system_num <-
as.numeric(as.factor(parental_care_data$care_system))</pre>
```

To account for surveyor oversight while recording tending parents (i.e., misidentifying a bi-parental familiy as uni-parental), bi-parental status always trumped female_care or male_care in broods where there were observations of different states within a single <code>brood_period</code>. This step summarizes all the observations a given brood and assigns the lowest level observed (i.e., both_care = 1, female_care = 2, male_care = 3) to that brood. We were comfortable with <code>female_care</code> trumping <code>male_care</code> because female uni-parental care is a rare in plovers, so it is a conservative approach.

```
parental_care_summary <-
  parental_care_data %>%
  dplyr::group_by(population, brood_period, family_ID) %>%
  dplyr::summarise(care_system = care_system[which.min(as.numeric(care_system_num))])
```

Calculate the proportion of late families in each population that exhibit both_care, female_care, or male_care.

```
# create a matrix of the summary
care_summary <- as.matrix(sample_sizes[, -c(1,5)])</pre>
rownames(care_summary) <- sample_sizes[,1]</pre>
# calculate the proportions for each population
care_summary_prop <- prop.table(care_summary, 1)</pre>
care_summary_prop <- as.data.frame(matrix(as.numeric(care_summary_prop), ncol = 3))</pre>

```

Proportion of families with female care (orange), male care (green), or parental cooperation (white)

Hatching sex ratio

The hatching sex ratio represents "rho" in the matrix model and is calculated from a dataset (hatch-ing_sex_ratio.txt) that contains broads that met two criteria: 1) the broad size was the modal clutch size of the species, and 2) chicks were captured and sampled on the day of hatching. These criteria made sure to control for post-hatch broad mixing, which can occur in precocial species such as plovers.

First, for each population, we tested for significant deviations in the hatching sex ratio from parity. We used a binomial mixed-effects model that included *family_ID* as a random effect to control for the non-independence of siblings.

Kittlitz's plover:

```

Summarize the hatching sex ratio data. First, calculate the proportion of each brood that is male

Then calculate some summary statistics for each population. The population-specific HSR parameter is used as rho in the matrix later on.

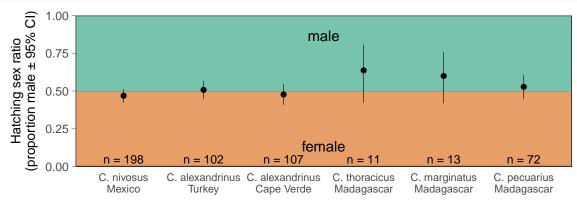

```

```

Quantifying mating system

To put our estimate of ASR in the context of breeding behavior, we quantified sex bias in mating system based on behavioral obersvations from the field. Females of *Charadrius* species are more likely to desert broods and seek serial mates than males. Thus, we expected that females would have more mates per year than males.

```
Step one: wrangle the data remove any cases in which one mate was not identified (i.e., "NA")
```

```
mating_df <-
breeding_data[which(!is.na(breeding_data$female) & !is.na(breeding_data$male)),]</pre>
```

determine the number of families used in the mating system analysis (i.e. the sample size)

```
length(unique(mating_df$family_ID))
#> [1] 1668
```

bind the two mates together to make a unique pair

```
mating_df$pair <- as.factor(paste(mating_df$female, mating_df$male, sep = "-"))</pre>
```

determine how many mating attempts each individual had each year

```
females <- reshape2::dcast(mating_df, female + population ~ year)
males <- reshape2::dcast(mating_df, male + population ~ year)</pre>
```

determine how many different mates each individual had over their lifetime in the population

```
number_males_p_female <-
   stats::aggregate(male ~ female, mating_df, function(x) length(unique(x)))
number_females_p_male <-
   stats::aggregate(female ~ male, mating_df, function(x) length(unique(x)))</pre>
```

join these two dataframes together and define as numeric

```
females <- dplyr::inner_join(females, number_males_p_female)
females[,c(3:16)] <-
    lapply(females[,c(3:16)], as.numeric)
males <- dplyr::inner_join(males, number_females_p_male)
males[,c(3:16)] <-
    lapply(males[,c(3:16)], as.numeric)</pre>
```

calculate the total number of mating attempts over each individual's lifetime

```
females$attempts <- rowSums(females[, c(3:16)])
males$attempts <- rowSums(males[, c(3:16)])</pre>
```

calculate the number of years breeding

```
females$years <- rowSums(females[, c(3:16)] > 0)
males$years <- rowSums(males[, c(3:16)] > 0)
```

filter out all individuals that only had one mating attempt

```
females_no_1 <- dplyr::filter(females, male != 1 | years != 1 | attempts != 1)
males_no_1 <- dplyr::filter(males, female != 1 | years != 1 | attempts != 1)</pre>
```

tidy up dataframes then bind them together

```
females_no_1$sex <- "Female"</pre>

Bootstrapping proceedure of stage- and sex specific survival

Specify where RMark should look on your computer for Program MARK. This may vary based on your operating system (e.g., Windows, Linux, Mac OS X, etc.). This website provides a nice workflow for installing Program MARK and linking it to your R interface based on which operating system you have.

```
MarkPath <- "/usr/local/bin/mark"

MarkViewer <- "nano"
```

Step one: Assign functions

The following two functions are needed to setup the projection matrix and estimate ASR. Load these before implementing the bootstrap simulation.

plover_matrix() builds the two-sex Lefkovitch matrix using the vital rates specified in the *demographic_rates* object.

```
# third row of matrix
0, NA, 0, NA,
# fourth row of matrix
0, 0,
demographic_rates$M_Juv_survl,
demographic_rates$M_Adt_survl),
nrow = length(stages), byrow = TRUE,
dimnames = list(stages, stages))
result
}
```

 $matrix_ASR()$ calculates the ASR of the population based on the two-sex two-stage projection matrix built by the $plover_matrix()$ function. Arguments in the function include: A is an two sex x by x projection matrix n is an x lengthed vector representing starting stage distribution (the default is a vector with 10 individuals in each stage)

```
matrix_ASR <-
  function(M, n = rep(10, nrow(M)), h = 1, k = 3,
           iterations = 1000, HSR = 0.5, plot = FALSE){
    # Number of stages in matrix
    x <- length(n)
    # Number of time steps to simulate
    t <- iterations
    # an empty t by x matrix to store the stage distributions
    stage <- matrix(numeric(x * t), nrow = x)</pre>
    # an empty t vector to store the population sizes
    pop <- numeric(t)</pre>
    # for loop that goes through each of t time steps
    for (i in 1:t) {
      # stage distribution at time t
      stage[,i] <- n
      # population size at time t
      pop[i] <- sum(n)
      # number of male adults at time t
      M2 <- stage[4, i]
      # number of female adults at time t
      F2 <- stage[2, i]
      # Female freq-dep fecundity of Female chicks
                      <- (k*M2)/(M2+(F2*h))*HSR
      # Female freq-dep fecundity of Male chicks
      M[(x/4)*3,x/2] \leftarrow (k*M2)/(M2+(F2*h))*HSR
      # Male freq-dep fecundity of Female chicks
      M[1,x]
                     <- (k*F2)/(M2+(F2*h))*HSR
      # Male freq-dep fecundity of Male chicks
                     <- (k*F2)/(M2+(F2*h))*HSR
      M[(x/4)*3,x]
      # define the new n (i.e., new stage distribution at time t)
      n <- M %*% n
      # define rownames of stage matrix
      rownames(stage) <- rownames(M)</pre>
      # define colnames of stage matrix
      colnames(stage) <- 0:(t - 1)</pre>
      # calculate the proportional stable stage distribution
      stage <- apply(stage, 2, function(x) x/sum(x))</pre>
      # define stable stage as the last stage
```

```
stable.stage <- stage[, t]</pre>
 }
  # calc ASR as the proportion of the adult stable stage class that is male
 ASR <- stable.stage[x]/(stable.stage[x/2] + stable.stage[x])
  if(plot)
 {
    # plot distrubution to assure that it is not chaotic
    matplot(rownames(t(stage)), t(stage), type='l', lwd=2, las=1)
  # make a list of results
 pop.proj <- list(ASR = ASR,</pre>
                   stable.stage = stable.stage,
                   stage.vectors = stage,
                   SSD_M2 = stable.stage[4],
                   SSD_F2 = stable.stage[2])
  # print the list as output to the function
 pop.proj
}
```

Step two: running the bootstrap

Each iteration will do the following computational steps:

A) Load the following function **bootstrap_data()** to randomly sample with replacement *juvenile_adult* dataset. Each bootstrapped sample has the same length as the original data.

B) The next function, **bootstrap_survival_ASR()**, runs the survival analyses and estimates the ASR of the bootstrapped sample created from **bootstrap_data()**. In the function, *juvenile_adult_boot* is the output dataframe from **bootstrap_data()** and *num_boot* is the bootstrap number in the loop (leave unspecified).

```
bootstrap_survival_ASR <- function(juvenile_adult_boot, num_boot, start_year, num_years, h, HSR, k) {

# specify the bootstrapped data sample (from the previous function)
juvenile_adult <- juvenile_adult_boot

# remove bird_ID column
juvenile_adult <- juvenile_adult[,-1]

# Create processed RMark data formatted as Cormack-Jolly_Seber with 2 groups
# (sex and age initally ringed), starting at year 2006, two age groups
# (first-years and adults) in which the first-year stage only lasts for
```

```
# one year.
juvenile_adult.proc <- RMark::process.data(juvenile_adult, model = "CJS",</pre>
                                             groups = c("sex", "age"),
                                             begin.time = start_year, age.var = 2,
                                             initial.age = c(1, 0))
# Create the design matrix from the processed mark-recapture datasets
juvenile_adult.ddl <- RMark::make.design.data(juvenile_adult.proc)</pre>
# adds first-year / adult age field to design data in column "Age"
juvenile_adult.ddl <- RMark::add.design.data(data = juvenile_adult.proc,
                                               ddl = juvenile_adult.ddl,
                                               parameter = "Phi",
                                               type = "age",
                                               bins = c(0, 1, num\_years),

```

To save your time with re-running the bootstrap, here are the four datasets produced by the bootstrap:

- output/AIC_table_juvenile_adult_boot_out.txt contains the bootstrap output for model selection of juvenile and adult survival based on the mark-recapture analysis run in Program MARK. Each row is a model fitted via maximum likelihood to the bootstrapped data sample of each iteration (iter). Phi describes the model structure for fitting annual survival. p describes the model structure for fitting annual encounter probability. npar reveals the number of parameters used in a given model. AICc is the Akaike Information Criteria statistic corrected for small sample size. DeltaAICc is the difference in AICc between a given model and the best fit model of a given iteration. weight describes the AIC weight of a given model. Deviance describes the deviance of a given model. population specifies the population from which the analysis of the iteration was based on.
- output/ASR_boot_out.txt contains the adult sex ratio estimates (ASR_boot_out) of each iteration of the bootstrap procedure. Each row represents an iteration (iter). population specifies the population from which the analysis of the iteration was based on.
- output/survival_rates_boot_out.txt contains the sex- and stage-specific survival estimates (estimate) of each iteration (iter) in the bootstrap procedure. Each row represents a given sex and stage (sex_age) in a given iteration. population specifies the population from which the analysis of the iteration was based on.

```
setwd("~/Dropbox/Luke/R_projects/Plover_ASR_Matrix_Modeling")

ASR_boot_out <-
    read.table("output/ASR_boot_out_final.txt", header = TRUE)</pre>
```

Visualizations of bootstrap results

Sex-biases in survial across chicks, juveniles, and adults

We visualized sex-bias in stage-specific survival rates with violin plots. These plots are useful for illustrating the spread of the bootstrap distribution. We have also added the inter-quartile ranges as horizontal bars within

the violins. Before plotting, the sex-bias at each stage for each bootstrap iteration needs to be calculated. This is done with the **sex_diff_surv()** function and specifying the output list from the bootstrap above.

```
sex_diff_survival <- function(survival_rates_boot_out, pop_name) {</pre>
  # subset the data to include only the population of interest
  survival_rates_boot2 <- dplyr::filter(survival_rates_boot_out, population == pop_name)</pre>
  # make an empty datarame to store the results
  sex diff surv output <- data.frame(Adult = numeric(niter),</pre>
                                      Juvenile = numeric(niter))
  # for loop to go through each iteration and calculate the differece between
  # female and male survival rates for each stage.
  for(i in 1:niter){
    Adult <-
      survival_rates_boot2[which(survival_rates_boot2$iter == i &
                                    survival_rates_boot2$sex_age == "Male_Adult"), 2] -
      survival_rates_boot2[which(survival_rates_boot2$iter == i &
                                    survival_rates_boot2$sex_age == "Female_Adult"), 2]
    Juvenile <-
      survival_rates_boot2[which(survival_rates_boot2$iter == i &
                                    survival_rates_boot2$sex_age == "Male_Juvenile"), 2] -
      survival_rates_boot2[which(survival_rates_boot2$iter == i &
                                    survival_rates_boot2$sex_age == "Female_Juvenile"), 2]
    sex_diff_surv_output[i, 1] <- Adult</pre>
    sex_diff_surv_output[i, 2] <- Juvenile</pre>
  }
  # restructure the output and lable columns
  sex_diff_surv_output <- reshape2::melt(data = sex_diff_surv_output)</pre>

Life table response experiment on ASR

Perturbation analyses provide important information about the relative effect that each component of a matrix model has on the population-level response, in our case ASR. To assess how influential a sex bias in parameters associated with each of the three life stages was on ASR dynamics, we employed a life-table response experiment (LTRE). A LTRE decomposes the difference in response between two or more "treatments" by weighting the difference in parameter values by the parameter's contribution to the response (i.e. its sensitivity), and summing over all parameters (Caswell 2001). Here, we compared the observed scenario, to a hypothetical scenario whereby all female survival rates were set equal to the male rates and the hatching sex ratio was set to 0.5. Thus, our LTRE identifies the drivers of ASR bias by decomposing the difference between the ASR predicted by our model and an unbiased ASR (Veran & Beissinger 2009).

The following two functions need to be specified first:

sensitivity_analysis() determines the sensitivities of each parameter in the non-linear two-sex matrix model. It does this by perturbing each parameter independently and simulating the matrix until the stable stage is achieved and the ASR can be determined. After all perturbations have been tested, a spline of the response vs. perturbated values is found and the tangent of this spline at the observed parameter value is defined as a given parameter's sensitivity.

```
sensitivity_analysis <-
  function(vital rates, matrix str, h = 1, k = 3, HSR, niter = 1000, ASR){
    # make a list of all parameters
    vr <-
      list(F_Juv_survl = vital_rates$F_Juv_survl,

Define vital rates of the M prime matrix (i.e., average between a "control matrix" and the "treatment matrix"). The control matrix is a matrix in which the female vital rates are set to the male vital rates, and the treatment matrix is the matrix containing the sex-specific values estimated from the field (see formula 8 on page 133 of Veran and Beissinger (2009)). The M-prime matrix is the average matrix of the treatment and control matricies. We also tested a scenario whereby the control matrix consisted of female-only rates (i.e., the male rates were set to the female rates).

```
# Set to male rates
KIP VR mprime male <-
             list(F_Juv_survl = (dplyr::filter(survival_rates_boot_summary,

Association between ASR and parental cooperation

To test the relationship between ASR bias and parental cooperation, we conducted a regression analysis of the following model:

$$P(cooperation) = \beta_0 + \beta_1 A + \beta_2 A^2 + \epsilon$$
$$P(male\ only\ care) = \beta_0 + \beta_1^A + \epsilon$$
$$P(female\ only\ care) = \beta_0 - \beta_1^A + \epsilon$$

where P is the proportion of families exhibiting parental cooperation, β_i are the regression parameters (i.e. intercept and coefficients), A is the ASR, and ϵ is random error. We chose a quadratic and exponetial models a priori as we expected maximum parental cooperation at unbiased ASR but minimum cooperation at both male- and female-biased ASRs, and a non-linear increase in uni-parental care by the abundant sex under biased ASR. These relationships were assessed with a bootstrap procedure that incorporated uncertainty in our estimates of ASR and parental care. Each iteration of the bootstrap (i) randomly sampled an ASR value from the 95% confidence interval of each population shown in Fig. 2b, (ii) randomly sampled a parental care value from the truncated 95% confidence interval of each population shown in Supplementary Table 2, then (iii) fitted the regression model. We ran 1,000 iterations of the bootstrap and evaluated overall relationships by visualizing the central tendency of the regressions. Due to our limited sample size (N = 6 populations), we consider this regression as exploratory.
